Keywords: NATCOM Inventory Seasonally integrated flux Paddy water regimes Organic amendment

ABSTRACT

A state-wise assessment of methane (CH₄) budget for Indian paddies, based on a decadal measurement data across India is presented for the calendar year (CY) 1994, the base year for India's Initial National Communication (NATCOM) to the United Nations Framework Convention on Climate Change (UNFCCC), along with national trend from CY 1979 to 2006. The NATCOM CH₄ emission factors (EFs) for Indian paddy cultivation areas, generally having less than 0.7% of soil organic carbon (SOC), have been estimated as 17.48 \pm 4 g m $^{-2}$ for irrigated continuously flooded (IR-CF), 6.95 \pm 1.86 g m $^{-2}$ for rain-fed drought prone (RF-DP), 19 \pm 6 g m $^{-2}$ for rain-fed flood prone (RF-FP) and deep-water (DW), 6.62 \pm 1.89 g m $^{-2}$ for irrigated intermittently flooded single aeration (IR-IF-SA) and 2.01 \pm 1.49 g m $^{-2}$ for IR-IF multiple aeration (MA) paddy water regimes. The state-wise study for 1994 has indicated national CH₄ budget estimate of 4.09 \pm 1.19 Tg y $^{-1}$ and the trend from 1979 to 2006 was in the range of 3.62 \pm 1 to 4.09 \pm 1.19 Tg y $^{-1}$. Four higher emitting or "hot spot" states (West Bengal, Bihar, Madhya Pradesh and Uttar Pradesh) have accounted for 53.9% of total CH₄ emission with RF-FP paddy water regime as the major contributor. CH₄ emissions were enhanced by factors such as SOC (~1.5 times due to increase in SOC by ~1.8 times), paddy cultivars (~1.5 times), age of seedlings (~1.4 times), and seasons (~1.8 times in Kharif or monsoon than in Rabi or winter season).

1. Introduction

Paddy fields are considered to be one of the important anthropogenic sources of atmospheric methane (CH₄). Methane emissions from paddy fields, which depend on many factors (Schutz et al., 1989; Yagi and Minami, 1990; Parashar et al., 1991, 1993; Sass et al., 1991; Cicerone et al., 1992; Adhya et al., 1994; Baruah et al., 1997; Satpathy et al., 1997; Khalil et al., 1998), arises due to the anaerobic decomposition of organic materials in the flooded soil and escapes to the atmosphere mainly by diffusive transport through the paddy plants (Nouchi et al., 1990) during the growing season. 15% of the 150 Mha global paddy harvest area (HA) are upland paddy fields which are not flooded and therefore do not emit

 ${\rm CH_4}$. Other paddy fields consisting of irrigated, rain-fed and deepwater paddy water regimes constitute an area of nearly 127 Mha of which over 90% is in Asia (Huke, 1982; Gupta et al., 2002) with maximum HA in India (42.2 Mha). Amount of global ${\rm CH_4}$ emitted from paddy fields is $60 \pm 40 \, {\rm Tg} \, {\rm y}^{-1}$ (Houghton et al., 1997).

National Physical Laboratory (NPL) had estimated (Mitra, 1991) a value of 3 Tg y^{-1} for CH₄ emission in India on the basis of measurements done upto 1990 at various paddy-growing regions in the country (Parashar et al., 1991). Methane campaign 1991 (MC-1991) observations had indicated CH₄ emission budget estimate of around $4 \pm 2 \text{ Tg y}^{-1}$ for Indian paddy fields. MC-1991, methane Asia campaign (MAC-1998) reports and several other papers (Mitra, 1991, 1992, 1996; Parashar et al., 1994a; Gupta and Mitra, 1999; Gupta et al., 2002) have so far documented the CH₄ budget estimate of $3.64 \pm 1.26 \text{ Tg y}^{-1}$, based on the flux data available upto 1999 from Indian paddy fields. This paper presents our study to

develop national communication (NATCOM) CH₄ emission factors (EFs) for Indian paddy fields and evolve trend of national CH₄ emission inventory from 1979 to 2006 with detailed state-wise analysis for the year 1994, which was the base year for reporting in the Initial National Communication to United Nations Framework Convention on Climate Change (UNFCCC).

2. Methodology adopted for methane emission inventory

The annual CH₄ emission from paddy fields has been estimated, using Inter-governmental Panel on Climate Change (IPCC) 1996 guidelines, as the product of the HA under different paddy water regimes as classified by IPCC with the corresponding seasonally integrated CH₄ flux ($E_{\rm sif}$) (Houghton et al., 1997). The total budget is the sum of resulting CH₄ emission from each paddy water regimes and can be formulated as:

$$F_c = \sum_i \sum_j \sum_k \cdots (E_{sif})_{ijk\cdots} \times A_{ijk\cdots} \times 10^{-12}$$

where, F_c is the total estimated emission of CH₄ in Tg y⁻¹ for different paddy water regimes i, j, k...[like, irrigated continuously flooded (IR-CF), rain-fed drought prone (RF-DP), rain-fed flood prone (RF-FP), deep-water (DW), irrigated intermittently flooded single aeration (IR-IF-SA) and IR-IF- multiple aeration (MA)], $E_{\rm sif}$ is the seasonally integrated CH₄ flux for these corresponding water regimes under a paddy-cropping season in g m⁻² and A_{ijk} is the annual paddy HA in m² under such water regimes.

2.1. Emission factors for IPCC paddy water regimes

Emission data generated in the country mainly involved manual sampling using static box or chamber technique over the entire paddy-cropping season, in major paddy-growing regions of the country apart from some data generated at Delhi and Cuttack utilizing automatic sampling systems of International Rice Research Institute (IRRI). The Indian data of CH_4 $E_{\rm sif}$ from paddy cultivation, post MAC 1998, has been updated upto year 2002 (Table 1), which includes measurement data obtained under

recent national campaign-2002 (in NC-2002, an extensive study was conducted in a coordinated network mode involving 10 institutes/universities in India covering the widest possible representative paddy areas) under India's NATCOM project and also data published in scientific papers (Singh et al., 1998; Rath et al., 1999). The quality and accuracy of the methane data generated during NC-2002 by the participating institutes has been ensured by calibrating the gas chromatographs methane analysis of the participating institutes by using methane gas standards 'BND 1601 methane in nitrogen' (a certified Indian Reference material) having national (NPL-India) traceability. As a measure of quality assurance/quality control (QA/QC) of the data generated by the participating institutes, a round robin inter-comparison for methane standard sample (BND 1601 methane in nitrogen) was also organized. The values of the institutes were found to be within the acceptable range of 2 Z-score. The Z-score, based on robust statistics, is a normalized value, which gives a score to each result relative to the other numbers in the group and is proposed by the National Association of Testing Authorities, Australia in 1996

(NATA, 1996). Table 1 provides the details of the study stations, number and year of seasonal flux observations, paddy variety, fertilizer/manure applied, paddy water regimes, $E_{\rm sif}$ and the corresponding references. The NC-2002 results, average of its participating institutes' E_{sif} from respective IPCC defined paddy water regimes without any organic amendments and representative of actual farmer field's soil and practices (Table 1), when integrated with earlier decadal data from 1991 to 1999 (Table 2) (Singh et al., 1998; Rath et al., 1999; Gupta et al., 2002), have yielded the new CH₄ E_{sif} values which are termed as NATCOM EFs (Fig. 1 and Table 2). Indian paddy cultivation areas, which consist of mainly low to medium levels (<0.7%) of soil organic carbon (SOC) (Velayutham et al., 2000; Gupta et al., 2002), indicated for different paddy water regimes without any organic amendments, NATCOM EFs of $17.48 \pm 4 \,\mathrm{g m^{-2}}$ for IR-CF, $6.95 \pm$ $1.86~{\rm g~m^{-2}}$ for RF-DP, $19\pm 6~{\rm g~m^{-2}}$ for RF-FP and DW, $6.62\pm 1.89~{\rm g~m^{-2}}$ for IR-IF-SA and $2.01\pm 1.49~{\rm g~m^{-2}}$ for IR-IF-MA (Table 2). A comparison of NATCOM EFs with MAC-1998 and IPCC-1996 default values is given in Table 2.

2.2. Harvest area activity data under IPCC paddy water regimes

Published government documents and reports have been used for activity data input values to the extent possible, as a measure of QA/QC practice. National (1979–2006) and state-wise (1994) financial year paddy HA statistics (CMIE, 2001; Agricultural Statistics at a Glance, 2002; Agricultural Statistics at a Glance, 2006) have been converted to calendar year (CY), which were then classified into 15% upland and the remaining 85% lowland (Table 3A and B) which has been further sub-categorized into 32% rain-fed and 53% irrigated HA. These have been further sub-classified

according to available country and states area statistics (WRI, 1991; Bolin, 1995; IRRI, 1995; Parashar et al., 1996; Houghton et al., 1997; Parashar et al., 1997; CMIE, 2001; Agricultural Statistics at a Glance, 2002; Gupta et al., 2002; Agricultural Statistics at a Glance, 2006). Out of the total area under rain-fed category, 16% has been assigned to FP that includes 6% under deep-water regime (Khush, 1984) and remaining 16% to DP. The irrigated areas (IA) (CMIE, 2001; Agricultural Statistics at a Glance, 2002; Agricultural Statistics at a Glance, 2006) are divided into 16% CF and 37% IF of the total HA (Houghton et al., 1997). Intermittently flooded paddy HA is further classified into SA and MA, which are prevalent in the

northern and western regions of India. MA occurs due to high water percolation rates of sandy-loam soils (Mitra, 1992; Baruah et al., 1997; Parashar et al., 1997) and non-availability of timely irrigation, making it highly variable. In the absence of documentation of paddy HA under these water regimes, the apportionment of IF paddy HA to 23% SA and 14% MA involved bottom-up approach and expert judgement for base year 1994, by using district level HA for major CH₄ emitting states, which considerably reduced the uncertainty. The national HA activity data from 1979 to 2006 and state-wise HA activity data for 1994 are presented in Table 3A

and B, respectively. The flow diagram of the methodology adopted for CH_4 emission inventory from Indian paddy fields is presented in Fig. 1.

2.3. Experimental design for development of enhancement factors

The experimental setups at the participating institutes under NC-2002 were designed with the aim to develop enhancement factors (the ratio of the maximum emission to the minimum emission) for different parameters affecting methane emission. To

- # It is 'Mean \pm standard deviation' in the value (** \pm **).

P.K. Gupta et al./Chemosphere xxx (2008) xxx-xxx

study the effect of SOC on $E_{\rm sif}$, experiments were planned at farmers' field at Dungrauli, Meerut (Uttar Pradesh). Similarly, to study the effect of rice cultivars and seedling age on $E_{\rm sif}$, experiments were carried out at CRRI research farms, Cuttack (Orissa) and the effect of growth season on $E_{\rm sif}$ has been studied at Lakshmi-kantapur, IRPE (West Bengal) (Table 1). The enhancement factor results are presented in Table 4 and discussed in Section 3.2.

3. Results and discussion

3.1. Methane emission inventory and "hot spots"

Using NATCOM EFs, the trend of national CH_4 emission inventory from paddy fields during 1979 to 2006 has indicated emission estimates and the variability in the range of 3.62 ± 1 to $4.09\pm1.19\,\mathrm{Tg}\,\mathrm{y}^{-1}$ (Table 3A and Fig. 2A-i), with an insignificant growth rate of $0.004\,\mathrm{Tg}\,\mathrm{y}^{-1}$ (Fig. 2A-i). Uncertainty ranges in the methane emission estimates under different paddy water regimes for the period 1979–2006 are shown in Fig. 2A-ii. For the year 1994, state-wise CH_4 emission estimates along with their uncertainty ranges have indicated, using NATCOM EFs, a total national budget estimate of $4.09\pm1.19\,\mathrm{Tg}\,\mathrm{y}^{-1}$ (Table 3B and Fig. 2B-i) which is more precise with reduced uncertainty compared to the previous estimates (Gupta et al., 2002), because of the detailed classification of paddy HA under different water regimes, down to district level for major CH_4 emitting states. 1994 CH_4 emission estimate shows an increase compared to the other years (Table

3A and Fig. 2A-i) because of the up-scaling of district level HA activity data to state level for various paddy water regimes, whereas for other years state level HA activity data has been used. Using IPCC-1996 EFs, the 1994 CH₄ budget estimate was estimated to be 4.49 Tg y^{-1} . The states in India have been ranked according to their cumulative emissions in descending order (Fig. 2B-ii) and the relatively high emitting (>0.5 Tg y⁻¹) states were termed as "hot spots" (Fig. 2B-i). Cumulative CH₄ emissions and their variability from various paddy water regimes for various states for the year 1994 are shown in Fig. 2B-ii. The results indicated that the four "hot spot" states (CH₄ emission >0.5 Tg y⁻¹) namely West Bengal, Bihar, Madhya Pradesh and Uttar Pradesh, accounted for nearly 53.9% of national CH₄ budget for 1994 $(4.09 \pm 1.19 \text{ Tg y}^{-1})$ The RF-FP water regime in these four states is the major contributor with 41% share (Fig. 2B-iii). However, at national level for the year 1994, maximum emissions are contributed from irrigated paddy water regimes with similar emission contribution (29.6%) from both RF-FP and IR-CF paddy water regimes (Table 3B).

3.2. Enhancement factors

High SOC content increases CH₄ production and emission by providing more carbon substrate. Since Indian paddy soils consist of mainly low to medium levels of SOC (Gupta et al., 2002), high SOC soils are not taken into account for Indian CH₄ budget estimates. However, during the NATCOM studies, influence of SOC variation on CH₄ flux has been studied for similar paddy cultivars,

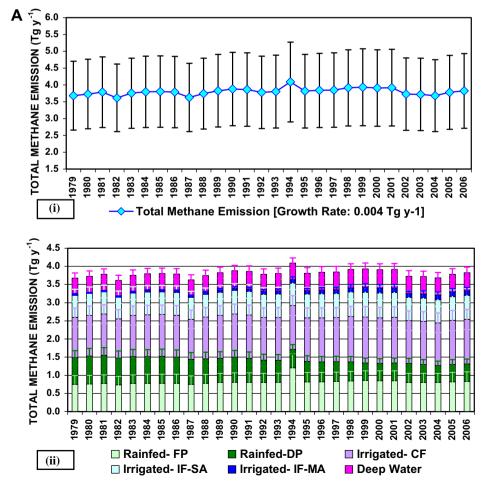

Fig. 2. (A) Methane emissions from Indian paddy fields from 1979 to 2006. (i) Variability in methane emissions, (ii) variability in cumulative methane emissions from Indian paddy water regimes. (B) Methane emissions from Indian states' paddy fields for the year 1994. (i) Methane emissions map showing the "hot spots" in red, (ii) variability in cumulative methane emissions from Indian states' paddy water regimes, (iii) % methane contribution by each paddy water regime of "hot spots".

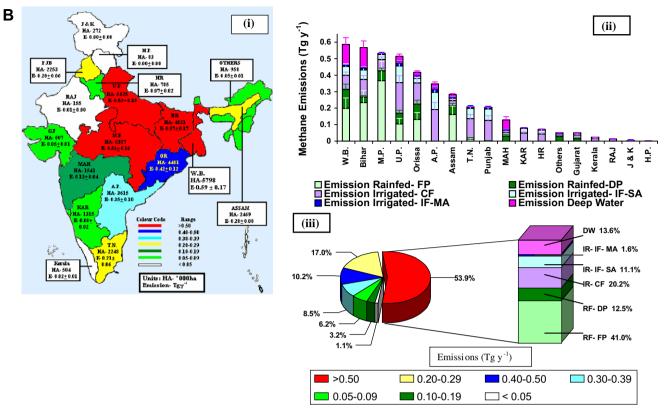

Fig. 2 (continued)

paddy water regimes and different doses of N applied as fertilizer supplements and have indicated that difference of \sim 1.8 times in SOC may result in \sim 1.5 times increase in CH₄ emissions (Table 4A). Cultivars also affect CH₄ emissions due to differences in root exudation and oxidation power as well as the gaseous exchange between atmosphere and anaerobic soil (Nouchi et al., 1990; Sethunathan, 1995). Studies have shown that rice cultivars could influence the CH₄ emissions by \sim 1.5 times (Table 4B-i), and different age of seedlings for same cultivar could influence the CH₄ emissions by \sim 1.4 times (Table 4B-ii), when planted under the same conditions. For the eastern part of country where two rice crops are cultivated in Kharif and Rabi seasons, it has been observed that CH₄ emissions during Kharif (July–November) or monsoon season is more as compared to Rabi (January–April) or winter season, by a factor of \sim 1.8 (Table 4C), when other factors were kept same.

Effect of IR-CF or IR-IF conditions for the same cultivar and soil regime in the presence of organic amendments can influence the CH₄ emissions (Gupta et al., 2002) by a factor of 1.3–6 (Table 4D-i and D-ii). As-per IPCC-1996 guidelines, organic amendments in flooded soils can increase CH₄ production and emission by a factor of 2 by providing more carbon substrate (Houghton et al., 1997). Limited Indian studies for the effect of organic amendment under different paddy water regimes have shown an enhancement in CH₄ emissions, for low organic carbon soils (Mitra et al., 2002), by a factor of 0.8–2.5 (Table 4E-i); and for high organic carbon soils, by a factor of 2.4 for IR-CF water regime (Table 4E-ii). CH₄ emissions from low and high organic carbon paddy soils for Asia have been given in Table 4E (Mitra et al., 2002).

4. Conclusions

The present study helps in the development of refined country specific CH₄ EFs from rice paddy fields along with emission

estimates and trend for India. The CH₄ EFs with reduced uncertainty were $17.48 \pm 4\,\mathrm{g}\,\mathrm{m}^{-2}$ for IR-CF, $6.95 \pm 1.86\,\mathrm{g}\,\mathrm{m}^{-2}$ for RF-DP, $19 \pm 6\,\mathrm{g}\,\mathrm{m}^{-2}$ for RF-FP and DW, $6.62 \pm 1.89\,\mathrm{g}\,\mathrm{m}^{-2}$ for IR-IF-SA and $2.01 \pm 1.49\,\mathrm{g}\,\mathrm{m}^{-2}$ for IR-IF-MA paddy water regimes. The Indian CH₄ budget for the base year 1994 was $4.09 \pm 1.19\,\mathrm{Tg}\,\mathrm{y}^{-1}$ and the trend in estimates from 1979 to 2006 was in the range of $3.62 \pm 1-4.09 \pm 1.19\,\mathrm{Tg}\,\mathrm{y}^{-1}$. The "hot spot" states in India have been found to be West Bengal, Bihar, Madhya Pradesh and Uttar Pradesh with RF-FP paddy water regimes, which are the largest contributors. The HA activity data for IR-IF-SA and IR-IF-MA water regimes and for different enhancement factors like organic amendments and SOC, need to be surveyed and documented upto district level, for further refining and reducing the uncertainties in the CH₄ emission budget estimates from rice paddy fields in India.

Acknowledgements

We are deeply indebted to late Dr. A.P. Mitra, FRS and honorary Scientist of eminence at NPL, for his vision and guidance. We acknowledge the keen interest of Dr. Vikram Kumar, Director NPL. Authors acknowledge the support provided by Dr. P.K. Aggarwal of IARI, Dr. Nahar Singh, Mrs. Pratul Sharma, Mrs. V. Pradhan and Mrs. S. Koul. We gratefully acknowledge the contribution of the research personnel from our collaborating institutes in the generation of CH₄ flux data. Thanks are due to NATCOM Project of Ministry of Environment and Forests, Government of India, for supporting this activity.
